Early Timely Treatment of Class III Malocclusion

Peter Ngan

The protraction facemask has been widely used in the treatment of Class III malocclusion with maxillary deficiencies. However, the benefit of this early treatment modality is not clear. One of the reasons orthodontists are reluctant to render early orthopedic treatment in Class III patients is the inability to predict mandibular growth. The use of a single cephalometric radiograph to predict excessive mandibular growth has severe limitations. The use of serial cephalometric radiographs taken a few years after facemask treatment, and a Growth Treatment Response Vector (GTRV) analysis to individualize and enhance the accuracy in predicting excessive mandibular growth, is presented and proposed. This article discusses the rationale for early “timely” treatment of Class III malocclusion, the indications and contraindications for early Class III treatment, and provides a method of predicting excessive mandibular growth using the GTRV analysis.

The occurrence of Class III malocclusion is believed to be hereditary although environmental factors such as habits and mouth breathing may play a role. The prevalence of Class III malocclusion varies among different ethnic groups. The incidence in Caucasians ranges between 1% and 4% depending on the method of classifying the malocclusion and the age group evaluated. In Asian societies, the frequency of Class III malocclusions is higher due to a large percentage of patients with maxillary deficiency. The incidence ranges between 4% and 5% among the Japanese and 4% and 14% among the Chinese.

Individuals with Class III malocclusion may have combinations of skeletal and dentoalveolar components. According to Guyer and coworkers, 57% of the patients with either a normal or prognathic mandible showed a deficiency in the maxilla. Protraction facemask therapy has been advocated in the treatment of Class III patients with maxillary deficiency. The dental and skeletal effects of this appliance are well documented in the literature. However, one of the reasons orthodontists are reluctant to render early orthopedic treatment in Class III patients is the inability to predict mandibular growth. Patients who have received early orthopedic treatment could still require surgical treatment at the end of the growth period. The ability to identify Class III patients with excessive mandibular growth at an early age could help orthodontists to plan for future orthodontic care. The use of a single cephalometric radiograph to predict mandibular growth has limitations. Discriminant analysis from long-term results of early treatment identified several cephalometric variables such as the position of the mandible, corpus length, gonial angle, and ramal height that have predictive values. However, these predictive formulae are better in predicting successful outcomes than unsuccessful outcomes.

Rationale for Early Timely Treatment of Class III Malocclusions

The objective of early orthodontic treatment is to create an environment in which a more favorable dentofacial development can occur. The goals of early Class III treatment may include the following:

1. To prevent progressive irreversible soft tissue or bony changes. Class III malocclusion is often accompanied with an anterior crossbite. Uncorrected anterior crossbite may lead to abnormal wear of the lower incisors, dental compensation of mandibular incisors, leading to thinning of the labial alveolar plate and/or gingival recession.

2. To improve skeletal discrepancies and provide a more favorable environment for future growth. Excessive mandibular growth is often accompanied by dental compensation of the mandibular incisors. Early orthopedic treatment using facemask or chin cup therapy
improves the skeletal relationships, which in turn minimize excessive dental compensation such as overclosure of the mandible and retroclination of the mandibular incisors.

3. To improve occlusal function. Class III malocclusion with an anterior crossbite is often accompanied by a functional shift. Early orthopedic treatment may help in eliminating centric occlusion/centric relation (CO/CR) discrepancies and avoid adverse growth potential.

4. To simplify phase II comprehensive treatment. In mild and moderate Class III patients, early orthodontic or orthopedic treatment may eliminate the necessity for orthognathic surgery treatment. Even if surgery is eventually needed, early correction of the transverse dimension and maximizing the growth potential of the maxilla may minimize the extent of the surgical procedures.

5. To provide more pleasing facial esthetics, thus improving the psychosocial development of a child.23 Studies have shown that treatment with facemask and/or chin cap improves lip posture and facial appearance.24-25

**Indications and Contraindications for Early Class III Treatment**

Turpin developed a list of positive and negative factors to aid in deciding when to intercept a developing Class III malocclusion.26 The positive factors include good facial esthetics, mild skeletal disharmony, no familial prognathism, presence of anteroposterior functional shift, convergent facial type, symmetric condylar growth, and growing patients with expected good cooperation. The negative factors include poor facial esthetics, severe skeletal disharmony, familial pattern established, no anteroposterior shift, divergent facial type, asymmetric condylar growth, growth complete, and poor cooperation. Turpin recommends that early treatment should be considered for a patient that presents with positive characteristics. For individuals who present with negative characteristics, treatment can be delayed until growth is completed.26 Patients should be aware that surgery may be needed at a later date, even when an initial phase of treatment may be successful.

**Early Treatment of Skeletal Class III Malocclusions**

**Chin Cup Therapy**

Skeletal malocclusion with a relatively normal maxilla and a moderately protrusive mandible may be treated with the use of a chin cup. This treatment modality is popular among the Asian population because of its favorable effects on the sagittal and vertical dimensions. The objective of early treatment with the use of a chin cup is to provide growth inhibition or redirection and posterior positioning of the mandible.

The orthopedic effects of a chin cup on the mandible include redirection of mandibular growth vertically, backward repositioning (rotation) of the mandible, and remodeling of the mandible with closure of the gonial angle. To date, there is no agreement in the literature as to whether chin cup therapy may or may not inhibit the growth of the mandible.27-29 However, chin cup therapy has been shown to produce a change in the mandible associated with a downward and backward rotation and a decrease in the angle of the mandible.28-31 In addition, there is less incremental increase in mandibular length together with posterior movement of the mandible. Because of the backward mandibular rotation of the mandible, control of vertical growth is difficult to manage, especially in long-face patients.

Chin cups are divided into two types: the occipital-pull chin cup that is used for patients with mandibular protrusion and the vertical-pull chin cup that is used in patients presenting with a steep mandibular plane angle and excessive anterior facial height. Most of the reported studies recommended an orthopedic force of 300 to 500 g per side.5,32,33 Patients are instructed to wear the appliance 14 hours per day. The orthopedic force is usually directed either through the condyle or below the condyle.

Evidence suggests that treatment of mandibular protrusion is more successful when it is started in the primary or early mixed dentition.30,32,34 The treatment time varies from 1 year to as long as 4 years, depending on the severity of the malocclusion. The stability of chin cup treatment remains unclear. Several investigators reported a tendency to return to the original growth pattern after the chin cup is discontinued.33,36 Sugawara and coworkers published a report on the long-term effects of the chin cup on three groups of Japanese girls who started treatment at 7, 9, and 11 years of age.35 The authors found that patients who started at an early age had a catch-up mandibular displacement in a forward and downward direction before growth was completed. However, several investigators believe that early correction of anterior crossbite reinforces the horizontal growth of the maxilla and prevents deterioration of horizontal jaw relationships.33,34

**Protraction Facemask Therapy**

The protraction facemask has been used in the treatment of patients with Class III malocclusions and a maxillary deficiency. The facemask has an adjustable anterior wire that can accommodate a downward and forward pull on the maxilla with elastics. To minimize the tipping of the palatal plane, the protraction elastics are attached near the maxillary canines with a downward and forward pull of 30° from the occlusal plane.11,12 Maxillary protraction usually requires 300 to 600 g of force per side, depending on the age of the patient. Patients are instructed to wear the appliance for 12 hours per day.

In the mixed dentition, a banded or bonded expansion appliance can be fabricated as anchorage for maxillary protraction. The expansion appliance is activated twice daily (0.25 mm per turn) by the patient or parent for 7 to 10 days. In patients with a more constricted maxilla, activation of the appliance is performed for 2 weeks or more.

Several facial sutures play an important role in the development of the nasomaxillary complex (frontomaxillary,
nasomaxillary, zygomaticotemporal, zygomaticomaxillary, pterygopalatine, intermaxillary, ethmomaxillary, and the lacrimal sutures). Animal studies have shown that the maxillary complex can be displaced anteriorly with significant changes in these facial sutures. Maxillary protraction, however, does not always result in forward movement of the maxilla. With the same line of force, different midfacial bones were displaced in different directions depending on the moments of force generated at the sutures. The center of resistance of the maxilla was found to be located at the distal contacts of the maxillary first molars one half the distances from the functional occlusal plane to the inferior border of the orbit. Protraction of the maxilla below the center of resistance produces counterclockwise rotation of the maxilla, which may not be favorable for patients with an open bite tendency.

Clinically, anterior crossbite can be corrected with 3 to 4 months of maxillary expansion and protraction depending on the severity of the malocclusion. Improvement in overbite and molar relationship can be expected with an additional 4 to 6 months of treatment. In a prospective clinical trial, overjet correction was found to be the result of forward maxillary movement (31%), backward movement of the mandible (21%), labial movement of the maxillary incisors (28%), and lingual movement of the mandibular incisors (20%). Over-correction of the overjet and molar relationship was highly recommended in anticipation of unfavorable mandibular growth. Overbite was improved by eruption of the posterior teeth. The total facial height was increased by inferior movement of the maxilla and downward and backward rotation of the mandible.

The question arises as to when is the best time to start protraction facemask treatment. The main objective of early facemask treatment is to enhance forward displacement of the maxilla by sutural growth. It has been shown by Melsen in her histological findings that the midpalatal suture was broad and smooth during the “infantile” stage (8 to 10 years of age) and the suture became more squamous and overlapping in the “juvenile” stage (10 to 13 years). Clinically, studies have shown that maxillary protraction was effective in the primary, mixed as well as early permanent dentitions. Several studies suggested that a greater degree of anterior maxillary displacement can be found when treatment was initiated in the primary or early mixed dentition. The optimal time to intervene a Class III malocclusion is at the time of the initial eruption of the maxillary incisors. A positive overjet and overbite at the end of the facemask treatment appears to maintain the anterior occlusion. Biologically, the circummaxillary sutures are smooth and broad before age 8 and become more heavily interdigitated around puberty.

Another question is whether early treatment can sustain subsequent mandibular growth during pubertal growth spurt. In a prospective clinical trial, protraction facemask treatment starting in the mixed dentition was found to be stable 2 years after the removal of the appliances. This is probably due to the overcorrection and the use of a functional appliance as retainer for 1 year. When these patients were followed for another 2 years 15 of the 20 patients maintained a positive overjet. In patients who relapsed back to a negative overjet, the mandible outgrew the maxilla in the horizontal direction. When these patients were followed for another 4 years (8 years after treatment until about 17.5 years of age), 14 of 20 patients (67%) maintained a positive overjet. For the patients who relapsed back into a reverse overjet, the mandible outgrew the maxilla by four times, compared with twice that in the stable group. These results suggest that in a random clinical trial when patients are followed until after completion of pubertal growth, two of three patients or 67% will have a favorable outcome. About one third of the patients might be candidates for orthognathic surgery later in life because of an unfavorable growth pattern. In an implant study, Bjork and Skieller examined the normal and abnormal growth of the mandible found that condylar growth does not follow a circular or logarithmic spiral course. It is characterized by individual variations both in the rate and growth direction. In addition, the rotation of the maxilla also varied from child to adulthood. This then raises the question as to whether it is possible to predict excess mandibular growth.

Growth Prediction of Class III Malocclusion

Several investigators have attempted to predict the progression of Class III malocclusions. Schulhof and associates compared several morphological characteristics of Class III patients with the norm (molar relationship, cranial deflection, porion location, and ramus positions). Using the Rocky Mountain Data System (Sherman Oaks, CA), if the sum of the deviations is greater than four, the computer warns the orthodontist of excessive mandibular growth. The accuracy of prediction is around 70% to 80%. Mito and coworkers suggested the use of cervical vertebral bone age to predict mandibular growth potential. The authors noted that this method is only useful in skeletal Class I patients with average growth pattern. Discriminant analysis of long-term results of early treatment identified several variables that had predictive values. Franchi and coworkers found the inclination of the condylar head, the maxillomandibular vertical relationship together with the width of the mandibular arch, could predict success or failure of early treatment. Ghiz and coworkers found that the position of the mandible, the ramal length, the corpus length, and the gonial angle can predict successful outcomes with 95% degree of accuracy. However, using a single cephalogram, the prediction formula can only accurately diagnose unsuccessful cases with only a 70% degree of accuracy. The present author proposes the use of serial cephalometric radiographs of patients taken a few years apart after facemask treatment and the use of a Growth Treatment Response Vector analysis to individualize and enhance the success of predicting excessive mandibular growth in Class III patients. The diagnostic procedure is usually performed during the early mixed dentition once a patient is diagnosed with maxillary deficiency. The patient will then be treated with maxillary expansion and a protraction facemask to eliminate the anterior crossbite, CO/CR discrepancy, and
maximize the growth potential of the nasomaxillary complex. The patient is followed for 3 to 4 years for growth observation. A GTRV analysis will then be performed during the early permanent dentition to allow clinicians to decide whether the malocclusion can be camouflaged by orthodontic treatment or whether a surgical intervention is necessary when growth is completed.

Growth Treatment Response Vector (GTRV) Analysis

Patients who presented with a Class III malocclusion and maxillary deficiency were treated with maxillary expansion and protraction facemask to eliminate anterior crossbite, CO/CR discrepancy, and maximize the growth potential of the nasomaxillary complex. Lateral cephalometric radiographs were taken after facemask treatment (Fig 1) and during the 3- to 4-year follow-up visit (Fig 2). The horizontal growth changes of the maxilla and mandible between the posttreatment radiograph and the follow-up radiograph are determined by locating the A point and B point on the first radiograph. The occlusal plane (O) was constructed by using the mesial buccal cusp of the maxillary molars and the incisal tip of the maxillary incisors as landmarks. The line AO and BO were then constructed by connecting A and B point perpendicular to the occlusal plane.

The GTRV ratio was calculated by using the following formula:

\[ \text{GTRV} = \frac{\text{Horizontal growth changes of the maxilla}}{\text{Horizontal growth changes of the mandible}} \]

The arrows show the growth vector of the maxilla and the mandible after facemask treatment (Fig 4). Clinicians can compare the growth changes of their Class III patients with the normal skeletal growth pattern derived from the Bolton Growth Study (Fig 5). The GTRV ratio of an individual with normal growth pattern from age 8 to 16 is calculated to be 0.77. That means the mandible usually exceed the maxilla in horizontal growth by 23% to maintain a good skeletal rela-
tionship. What about in patients with Class III growth pattern?

A study on 20 patients who were successfully treated with facemask therapy and 20 patients who were unsuccessfully treated with facemask therapy indicated that the GTRV ratio of the successful and unsuccessful groups were significantly different from each other ($P < 0.05$). The mean GTRV ratio for the successful group was $0.49 \pm 0.14$ with a range of $0.33$ to $0.88$. The mandible outgrew the maxilla by $51\%$ during this observation period compared with $23\%$ for individuals with normal skeletal growth pattern. The mean GTRV ratio for the unsuccessful group was $0.22 \pm 0.10$ with a range of $0.06$ to $0.38$. The mandible exceeded the maxilla in growth by $78\%$ compared with $23\%$ for individuals with normal skeletal growth pattern. These results suggest that Class III patients with maxillary deficiency and a GTRV ratio that falls between $0.33$ and $0.88$ can be successfully camouflaged with orthodontic treatment. Class III patients with excessive mandibular growth together with a GTRV ratio that falls below $0.38$ should be warned of the future need for orthognathic surgery.

Conclusions

It has been shown that in a random clinical trial when patients are followed until after completion of pubertal growth, one out of three patients may be candidates for orthognathic surgery later in life because of an unfavorable growth pattern. Early treatment of Class III patients with maxillary deficiency using appliances such as the protraction facemask can be used to eliminate anterior crossbite, CO/CR discrepancy, and maximize the growth potential of the nasomaxillary complex. In addition, it can be used together with the GTRV analysis as a tool to help clinicians in predicting patients with excessive mandibular growth that may not be able to be camouflaged with orthodontic treatment. Protraction facemask treatment is ideally performed in the early mixed dentition. A follow-up lateral cephalogram can be taken 2 to 3 years after completion of protraction facemask treatment to determine the horizontal growth of the maxilla and the mandible as well as the growth vector or direction. The Growth Treatment Response Vector (GTRV) ratio calculated during the early permanent dentition period will allow clinicians to inform patients whether malocclusion can be camouflaged with orthodontic treatment or if surgical treatment will be required at a later age.$^{10}$
